Action potential-dependent release of synaptic vesicles and short-term synaptic plasticity are dynamically regulated by the endogenous  $\text{Ca}^{2+}$  buffers that shape  $[\text{Ca}^{2+}]$  profiles within a presynaptic bouton. Calmodulin is one of the most abundant presynaptic proteins and it binds  $\text{Ca}^{2+}$  faster than any other characterized endogenous neuronal  $\text{Ca}^{2+}$  buffer. Direct effects of calmodulin on fast presynaptic  $\text{Ca}^{2+}$  dynamics and vesicular release however have not been studied in detail. Using experimentally constrained three-dimensional diffusion modeling of  $\text{Ca}^{2+}$  influx–exocytosis coupling at small excitatory synapses we show that, at physiologically relevant concentrations,  $\text{Ca}^{2+}$  buffering by calmodulin plays a dominant role in inhibiting vesicular release and in modulating short-term synaptic plasticity. We also propose a novel and potentially powerful mechanism for short-term facilitation based on  $\text{Ca}^{2+}$ -dependent dynamic dislocation of calmodulin molecules from the plasma membrane within the active zone.

## Introduction

Calmodulin (CaM) is a major neuronal protein that acts as a key mediator of multiple  $\text{Ca}^{2+}$ -dependent intracellular signaling cascades in the brain. CaM regulates synaptic transmission and synaptic plasticity via  $\text{Ca}^{2+}$ -dependent binding to its target proteins in both the pre- and the post-synaptic compartments. These include protein kinases, adenylyl cyclases, calcineurin, Munc13s, and voltage-gated  $\text{Ca}^{2+}$  channels (VGCCs) (Xia and Storm, 2005; Pang et al., 2010; Sun et al., 2010; Lipstein et al., 2013; Ben-Johny and Yue, 2014). It has been recently demonstrated that CaM binds  $\text{Ca}^{2+}$  ions with much faster kinetics than other major neuronal  $\text{Ca}^{2+}$  buffers such as calbindin-D28k (CB), parvalbumin, and calretinin (Faas et al., 2011). However, in comparison to the other buffers direct effects of CaM-dependent  $\text{Ca}^{2+}$  buffering on action potential (AP)-evoked presynaptic  $\text{Ca}^{2+}$  dynamics and vesicular release have not been systematically studied.

In this work we performed realistic, experimentally constrained model simulations of AP-evoked presynaptic  $\text{Ca}^{2+}$  dynamics and synaptic vesicle fusion in small excitatory synapses. We compared the relative contributions of  $\text{Ca}^{2+}$  buffering by CB and CaM to modulation of vesicular release probability and short-term synaptic plasticity. Our simulations demonstrate that, at physiologically relevant concentrations, fast  $\text{Ca}^{2+}$  binding to the N-lobe of CaM has a dominant effect in inhibiting AP-evoked vesicular release. We also show

that the predicted effect of CaM  $\text{Ca}^{2+}$  buffering on short-term synaptic plasticity strongly depends on the location and mobility of CaM molecules.

Finally, we propose a novel mechanism for a dynamic regulation of presynaptic strength based on  $\text{Ca}^{2+}$ -dependent interaction of CaM with membrane-associated proteins that contain the isoleucine–glutamine (IQ) binding motif (e.g., neuromodulin and VGCCs) (Alexander et al., 1988; Xia and Storm, 2005; Ben-Johny and Yue, 2014). Our simulations demonstrate that  $\text{Ca}^{2+}$ -induced dislocation of CaM molecules from the plasma membrane could lead to a significant reduction of  $\text{Ca}^{2+}$  buffering capacity within the active zone (AZ). This in turn, leads to an increase of vesicular release probability during repeated APs. Thus, AP-evoked dislocation of CaM may provide a powerful mechanism for short-term facilitation of synaptic transmission.

## Materials and Methods

### Modeling of Presynaptic $\text{Ca}^{2+}$ Dynamics

Three-dimensional modeling of dynamic AP-evoked presynaptic  $\text{Ca}^{2+}$  influx, buffering, and diffusion, on a millisecond timescale, was performed in the Virtual Cell (VCell) simulation environment (<http://vcell.org>) using the fully implicit finite volume regular grid solver and a 10 nm mesh. In contrast to the simplified steady-state and/or non-stationary single compartment models that are normally used to approximate presynaptic  $\text{Ca}^{2+}$  dynamics on tens to hundreds of milliseconds timescale (Neher, 1998; Sabatini and Regehr, 1998; Scott and Rusakov, 2006; Ermolyuk et al., 2012), no assumptions regarding  $\text{Ca}^{2+}$  buffer binding and/or diffusional equilibration were made in the VCell model used here. VCell simulations using a 10 nm mesh produced solutions for presynaptic  $\text{Ca}^{2+}$  dynamics at vesicular release sensors similar to those obtained in our previous work with a 5 nm mesh (Ermolyuk et al., 2013). The use of the larger mesh substantially increased the computation speed and allowed us to simulate  $\text{Ca}^{2+}$  dynamics in the whole presynaptic bouton on the longer time scale.

The presynaptic bouton was considered as a truncated sphere (**Figure 1A**) of radius  $R_{\text{bout}} = 0.3 \mu\text{m}$  (described by the equation  $[x^2 + y^2 + z^2 \leq 0.09] \cdot [z \leq 0.25]$ , all distances are in  $\mu\text{m}$ ). The AZ containing VGCCs was modeled as a circle of radius  $R_{\text{AZ}} = 0.16 \mu\text{m}$  situated in the center of the truncated plane  $z = 0.25 \mu\text{m}$ . VGCCs were evenly distributed within a rectangular cluster (40 by 80 nm) which was placed in the center of the AZ. The cluster contained 7 P/Q-type, 8 N-type, and 1 R-type VGCCs (Ermolyuk et al., 2013).

The model assumed  $\text{Ca}^{2+}$  binding to the three endogenous buffers present in the presynaptic bouton: CaM, CB, and ATP.  $\text{Ca}^{2+}$  interaction with free CaM was simulated using a two-step cooperative binding model to the N- and the C-lobes of CaM molecule (Faas et al., 2011):

$k_{\text{on}}^{(T),N} = 770 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{(T),N} = 1.6 \times 10^5 \text{s}^{-1}$ ,  $k_{\text{on}}^{(R),N} = 3.2 \times 10^4 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{(R),N} = 2.2 \times 10^4 \text{s}^{-1}$ ,  $k_{\text{on}}^{(T),C} = 84 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{(T),C} = 2.6 \times 10^3 \text{s}^{-1}$ ,  $k_{\text{on}}^{(R),C} = 25 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{(R),C} = 6.5 \text{s}^{-1}$ . The total average CaM concentration was  $[\text{CaM}]_{\text{tot}} = 100 \mu\text{M}$  (Faas et al., 2011). Depending on the type of simulation (as indicated in the text) CaM was considered either as a mobile buffer with diffusion coefficient  $D_{\text{CaM}} = 20 \mu\text{m}^2 \text{s}^{-1}$ , or as an immobile buffer which was either evenly distributed throughout the bouton volume or bound to the plasma membrane (within a 10 nm single layer adjacent to the bouton membrane in VCell simulations). In the case of CaM associated with neuromodulin we assumed that  $k_{\text{off}}^{(R),C}$  was increased 50-fold (Gaertner et al., 2004; Hoffman et al., 2014) ( $k_{\text{off}}^{(R),C} = 325 \text{s}^{-1}$ ).

Each CB molecule contained four independent  $\text{Ca}^{2+}$  binding sites (two fast and two slow) (Nagerl et al., 2000):

$k_{\text{on}}^{\text{CB,fast}} = 87 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{\text{CB,fast}} = 35.8 \text{s}^{-1}$ ,  $k_{\text{on}}^{\text{CB,slow}} = 11 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{\text{CB,slow}} = 2.6 \text{s}^{-1}$ . The diffusion coefficient for both  $\text{Ca}^{2+}$ -free and  $\text{Ca}^{2+}$ -bound CB molecules was  $D_{\text{CB}} = 20 \mu\text{m}^2 \text{s}^{-1}$  and the total CB concentration was  $[\text{CB}]_{\text{tot}} = 47.5 \mu\text{M}$  (Muller et al., 2005).

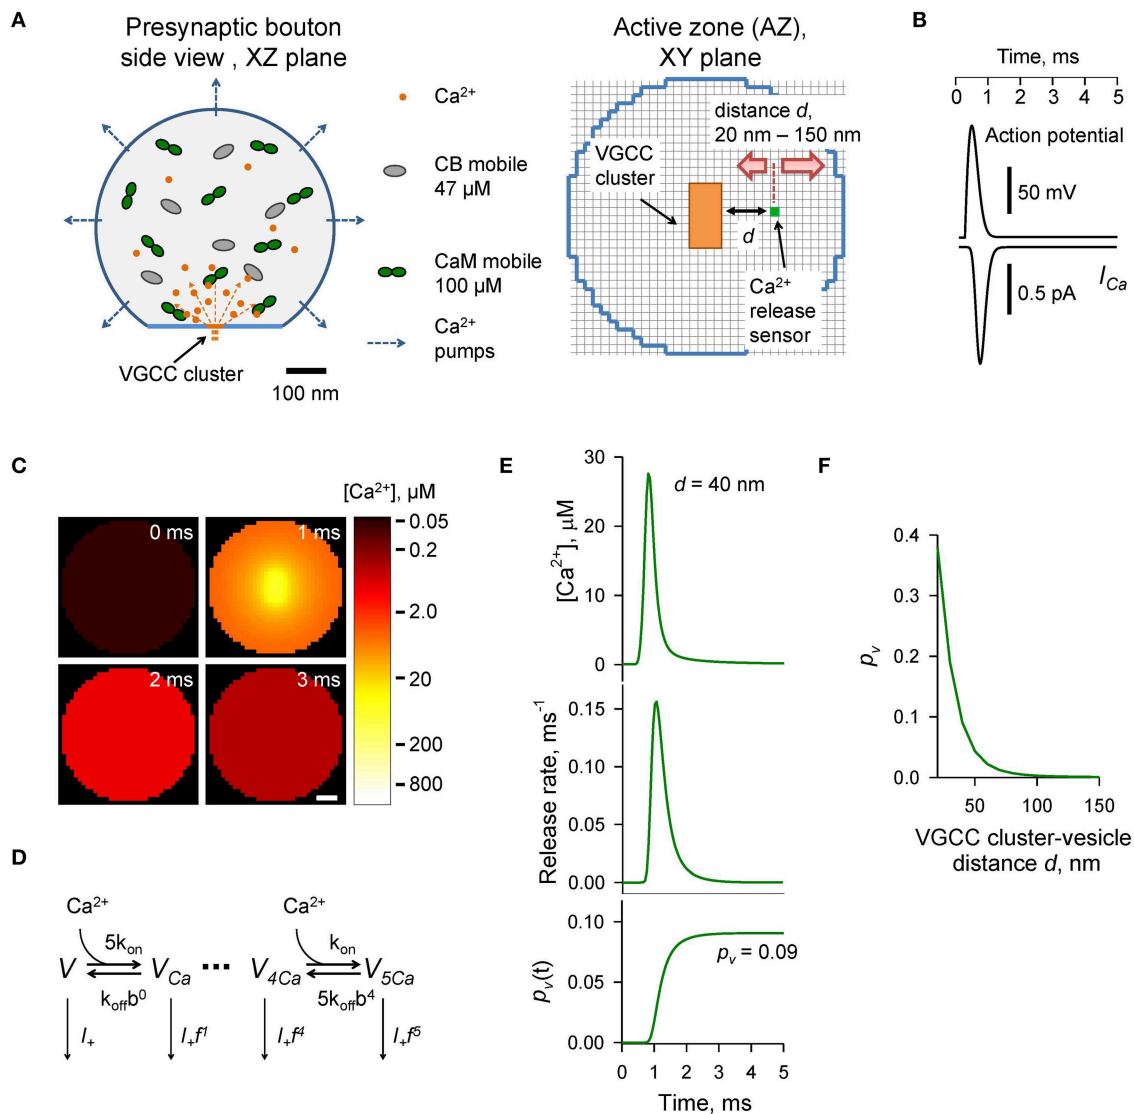

$\text{Ca}^{2+}$  binding to ATP was modeled as a second order reaction:

$k_{\text{on}}^{\text{ATP}} = 500 \mu\text{M}^{-1} \text{s}^{-1}$ ,  $k_{\text{off}}^{\text{ATP}} = 1.0 \times 10^5 \text{s}^{-1}$ . The diffusion coefficient of free and  $\text{Ca}^{2+}$  bound ATP was  $D_{\text{ATP}} = 220 \mu\text{m}^2 \text{s}^{-1}$  (Meinrenken et al., 2002). The total ATP concentration was  $[\text{ATP}]_{\text{tot}} = 0.9 \text{mM}$ , corresponding to  $58 \mu\text{M}$   $[\text{ATP}]_{\text{free}}$  at resting physiological conditions (assuming 1 mM intracellular  $[\text{Mg}^{2+}]$ ) (Faas et al., 2011).

$\text{Ca}^{2+}$  extrusion by the bouton surface pumps (excluding the AZ) was approximated by a first-order reaction:  $j_{\text{extr}} = -k_{\text{extr}} \cdot ([\text{Ca}^{2+}] - [\text{Ca}^{2+}]_{\text{rest}})$  (Matveev et al., 2006; Ermolyuk et al., 2013), with  $k_{\text{extr}} = 125 \mu\text{m} \text{s}^{-1}$  and  $[\text{Ca}^{2+}]_{\text{rest}} = 50 \text{nM}$ .

AP-evoked  $\text{Ca}^{2+}$  currents through P/Q-, N-, and R-type VGCCs were modeled in the NEURON simulation environment (Hines and Carnevale, 1997) using a six-state channel gating kinetic model of P/Q-, N-, and R-type VGCCs in hippocampal mossy fiber boutons (Li et al., 2007) as described in detail previously (Ermolyuk et al., 2013). The mean AP-evoked  $\text{Ca}^{2+}$  current at the VGCC cluster was approximated by averaging 500

Final AP-evoked vesicular release probability  $p_v$  is shown in the insert. This was determined as the horizontal asymptote of a cumulative probability after the AP (in practice we defined it as a value of  $p_v(t)$  at  $5 \text{ ms}$ ). **(F)** Dependency of  $p_v$  on distance  $d$ .

independent NEURON simulations of AP-evoked  $\text{Ca}^{2+}$  currents for each channel sub-type, followed by fitting the sum of average  $\text{Ca}^{2+}$  currents corresponding to 7 P/Q-type, 8 N-type, and 1 R-type VGCCs with the function  $I_{\text{Ca}}(t) = \frac{A}{t} \exp[-B \cdot [\ln(t/t_0)]^2]$ , where  $A = 9.2246 \times 10^{-4} \text{ pA s}$ ,  $B = 15.78$ ,  $t_0 = 8.036 \times 10^{-4} \text{ s}$  (Figure 1B). We did not consider any possible effects of AP waveform changes during repeated AP stimulations and assumed that the magnitude of  $\text{Ca}^{2+}$  influx was the same at

each AP. Access to the VCell simulations is available upon request.

## Modeling of $\text{Ca}^{2+}$ -triggered Synaptic Vesicle Fusion

Vesicular release rates were calculated using a previously published six-state allosteric model of  $\text{Ca}^{2+}$  activation of vesicle fusion in the calyx of Held (Lou et al., 2005) (Figure 1D). The

model parameters were:  $k_{on} = 1 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ ,  $k_{off} = 4 \times 10^3 \text{ s}^{-1}$ ,  $b = 0.5$ ,  $f = 31.3$ , and  $I_+ = 2 \times 10^{-4} \text{ s}^{-1}$ . The model was solved using a variable-order stiff multistep method based on the numerical differentiation formulas (function *ode15s* in MATLAB, MathWorks USA) for AP-evoked  $\text{Ca}^{2+}$  concentration profiles obtained in VCell simulations at each of the  $10 \times 10 \times 10 \text{ nm}$  voxels located immediately above the AZ plane (**Figure 1C**). MATLAB computer code is enclosed (Supplementary MATLAB code).

The time-dependent vesicular release probability at each voxel in the AZ was calculated as  $p_v(t) = 1 - \sum_i V_i(t)$ , where  $\sum_i V_i(t)$  is the sum of occupancies of all six model states  $V_i$  (**Figure 1D**). The release rate was then calculated as  $R_{rel} = dp_v(t)/dt$ . In this work we were specifically interested in dissecting the relative effects of CaM and CB on vesicular release and short-term facilitation. Therefore, we did not take into account any changes in the number of release-ready vesicles that occur during paired-pulse stimulation due to vesicle depletion and replenishment. We thus considered that at the onsets of both the first and second APs the vesicular release sensor was in  $\text{Ca}^{2+}$  unbound state  $V_{t=0ms} = V_{t=20ms} = (1, 0, 0, 0, 0, 0)$ . To account for sensitivity of AP-evoked release observed in small excitatory hippocampal and neocortical synapses to the slow endogenous buffer EGTA (e.g., Rozov et al., 2001; Ermolyuk et al., 2013), voxels located closer than 20 nm to the VGCC clusters were excluded from the analysis.

## Results

### Experimentally Constrained Model of AP-evoked Synaptic Vesicle Exocytosis in Small Central Synapses

To compare the effects of CB and CaM  $\text{Ca}^{2+}$  buffering on AP-evoked vesicular release and short-term synaptic plasticity we used a realistic experimentally constrained three-dimensional model of AP-evoked VGCC-mediated  $\text{Ca}^{2+}$  influx,  $\text{Ca}^{2+}$  buffering and diffusion, and  $\text{Ca}^{2+}$ -dependent activation of vesicular release sensors. The modeling framework consisted of two steps: simulation of buffered  $\text{Ca}^{2+}$  diffusion in the presynaptic bouton using VCell environment, and calculation of vesicular release rates and fusion probabilities  $p_v$  using an allosteric model of the  $\text{Ca}^{2+}$  activation of vesicle fusion developed in the calyx of Held (Lou et al., 2005) (Materials and Methods).

The presynaptic bouton was considered as a truncated sphere ( $R_{bout} = 0.3 \mu\text{m}$ ) with the AZ located at the truncated plane (**Figure 1A**). Immunogold electron microscopy has shown that P/Q-type VGCCs in small excitatory CA3 hippocampal synapses are mainly situated in small oval-shaped clusters with typical dimensions of 50–100 nm, and that the number of such clusters linearly scales with the size of the AZ (Holderith et al., 2012). To simplify our model we assumed that the AZ had only a single VGCC cluster of rectangular shape:  $40 \times 80 \text{ nm}$  (**Figure 1A**). Indeed, several studies have argued that for a given release-ready vesicle docked at the AZ its AP-evoked release probability  $p_v$  is mainly determined by the closest VGCC cluster (Meinrenken et al., 2002; Ermolyuk et al., 2013; Nakamura et al., 2015).

AP-evoked release in small central excitatory synapses is triggered by mixed populations of P/Q-, N-, and R-type VGCCs (Wu and Saggau, 1994; Reid et al., 1998; Li et al., 2007; Holderith et al., 2012; Sheng et al., 2012). Based on experimental data for the relative numbers of P/Q-, N-, and R-type VGCCs in small hippocampal boutons (Ermolyuk et al., 2013) and for the average channel density within VGCC clusters (Holderith et al., 2012) we considered that the VGCC cluster contains 7 P/Q-type, 8 N-type, and 1 R-type VGCCs. In this simplified model we did not take into account the stochastic behavior of individual VGCCs during an AP and assumed that all channels are evenly distributed within the VGCC cluster. Thus, total AP-evoked  $\text{Ca}^{2+}$  influx at the VGCC cluster was approximated as the sum of average  $\text{Ca}^{2+}$  currents corresponding to 7 P/Q-type, 8 N-type, and 1 R-type VGCCs (**Figure 1B** and Materials and Methods).

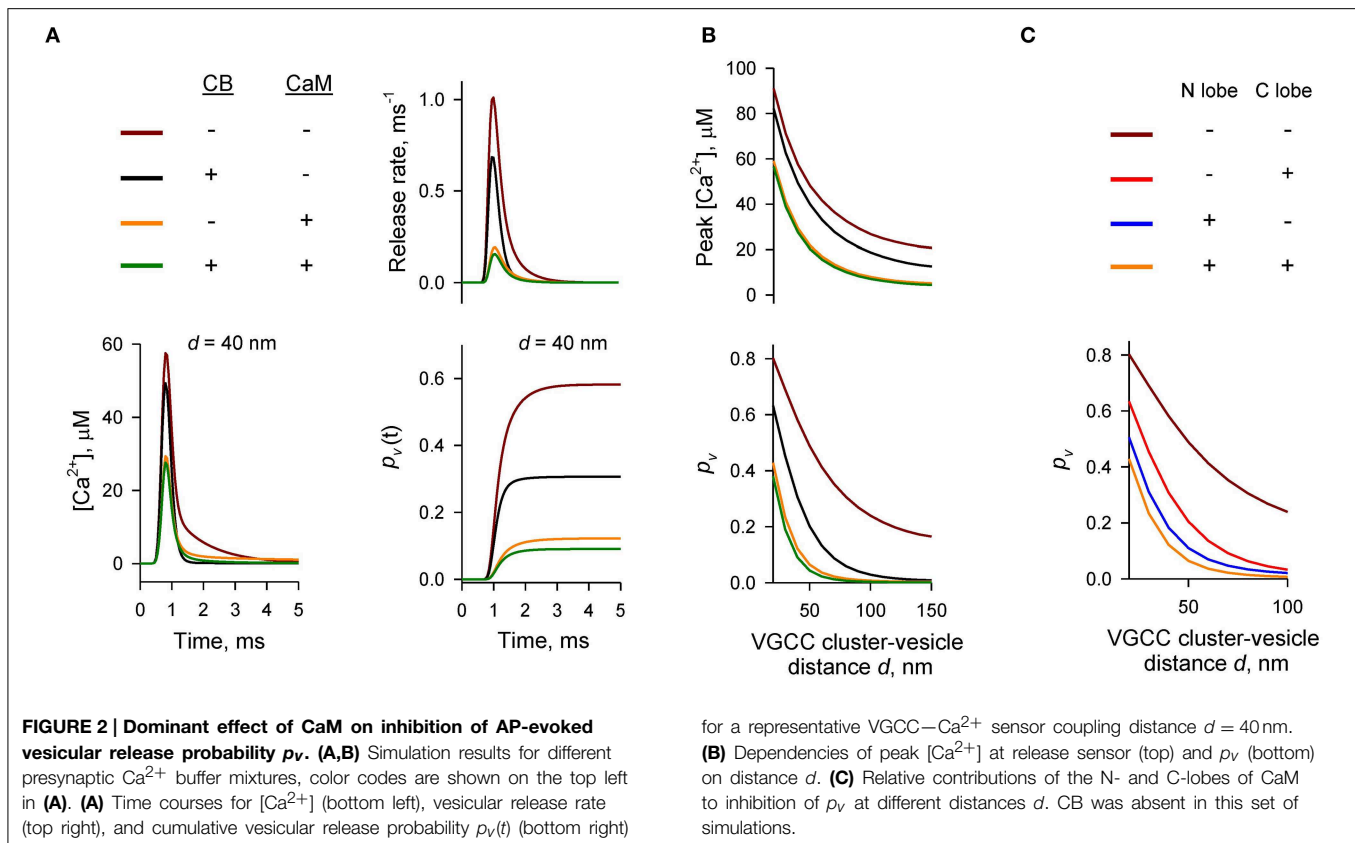

We considered that in addition to ATP the presynaptic bouton contains two major presynaptic  $\text{Ca}^{2+}$  buffers found in central excitatory synapses: CB [physiological  $[CB]_{tot} \sim 47.5 \mu\text{M}$ , total concentration of  $\text{Ca}^{2+}$  binding sites  $190 \mu\text{M}$ ; (Berggard et al., 2002; Jackson and Redman, 2003; Muller et al., 2005; Scott and Rusakov, 2006)] and CaM (physiological  $[CaM]_{tot} \sim 100 \mu\text{M}$ , total concentration of  $\text{Ca}^{2+}$  binding sites  $400 \mu\text{M}$ ; Faas et al., 2011). In the first set of simulations we assumed that CaM molecules are mobile and have the same coefficient of diffusion in  $\text{Ca}^{2+}$ -free and  $\text{Ca}^{2+}$ -bound states equal to that of CB ( $D_{CaM} = D_{CB} = 20 \mu\text{m}^2 \text{ s}^{-1}$ ).

To calculate the AP-evoked synaptic vesicle release probability  $p_v$  as a function of distance between the VGCC cluster and the vesicular release sensor (coupling distance  $d$ , **Figure 1A**) we extracted from the three-dimensional VCell model  $\text{Ca}^{2+}$  dynamics at the AZ (**Figure 1C**) and then calculated  $p_v$  at different  $d$  using the allosteric model of  $\text{Ca}^{2+}$ -triggered synaptic vesicle fusion (**Figure 1D**). Consistent with experimental data (Murthy et al., 2001; Ariel and Ryan, 2010; Ermolyuk et al., 2012) the model predicted that physiologically relevant  $p_v$ -values (0.05–0.15 range) should correspond to an average coupling distance  $d$  within a 30–50 nm range (**Figures 1E,F**).

### Dominant Effect of CaM $\text{Ca}^{2+}$ Buffering on AP-evoked Vesicular Release

To compare the relative contributions of CB and CaM to buffering of AP-evoked  $[\text{Ca}^{2+}]$  transients at the AZ (and, as a consequence, to inhibition of vesicular release) we performed simulations using different combinations of CB and CaM either absent or present at physiological concentrations (**Figures 2A,B**). The model predicted that each buffer on its own efficiently inhibited AP-evoked AZ  $[\text{Ca}^{2+}]$  transients and  $p_v$ . At a typical coupling distance  $d = 40 \text{ nm}$  CB caused  $\sim 50\%$  reduction of  $p_v$  (from 0.58 to 0.31) relative to control simulations without CB and CaM. CaM had even stronger inhibitory effect:  $\sim 80\%$  reduction of  $p_v$  at  $d = 40 \text{ nm}$  (from 0.58 to 0.12). Consistent with the steep power relationship between vesicular release rate and  $[\text{Ca}^{2+}]$  at the release sensors (Mintz et al., 1995; Lou et al., 2005)  $\text{Ca}^{2+}$  buffering by CB and CaM caused a non-additive supralinear reduction of  $p_v$ . Notably, addition of CB on top of CaM caused only a minor further decrease of  $p_v$  (e.g., from 80 to 85% at  $d = 40 \text{ nm}$ ).

We next compared the relative contributions of the fast  $\text{Ca}^{2+}$  binding to the CaM N-lobe (limiting rate constant  $k_{on}^{(T),N} = 770 \mu\text{M}^{-1} \text{s}^{-1}$ ) and the slower  $\text{Ca}^{2+}$  binding to the CaM C-lobe (limiting rate constant  $k_{on}^{(T),C} = 84 \mu\text{M}^{-1} \text{s}^{-1}$ ) to inhibition of  $p_v$ . Consistent with its  $\sim$  ten-fold higher  $\text{Ca}^{2+}$  binding rate the N-lobe had a dominant effect in reducing AP-evoked  $[\text{Ca}^{2+}]$  transients at the AZ and  $p_v$  (Figure 2C). The C-lobe on its own produced an inhibitory effect similar to that of CB.

Thus, our simulations show that fast synchronous AP-evoked vesicular release at synapses that contain both CB and CaM is mainly inhibited by fast  $\text{Ca}^{2+}$  binding to the N-lobe of CaM and that the CaM C-lobe and CB play only secondary roles.

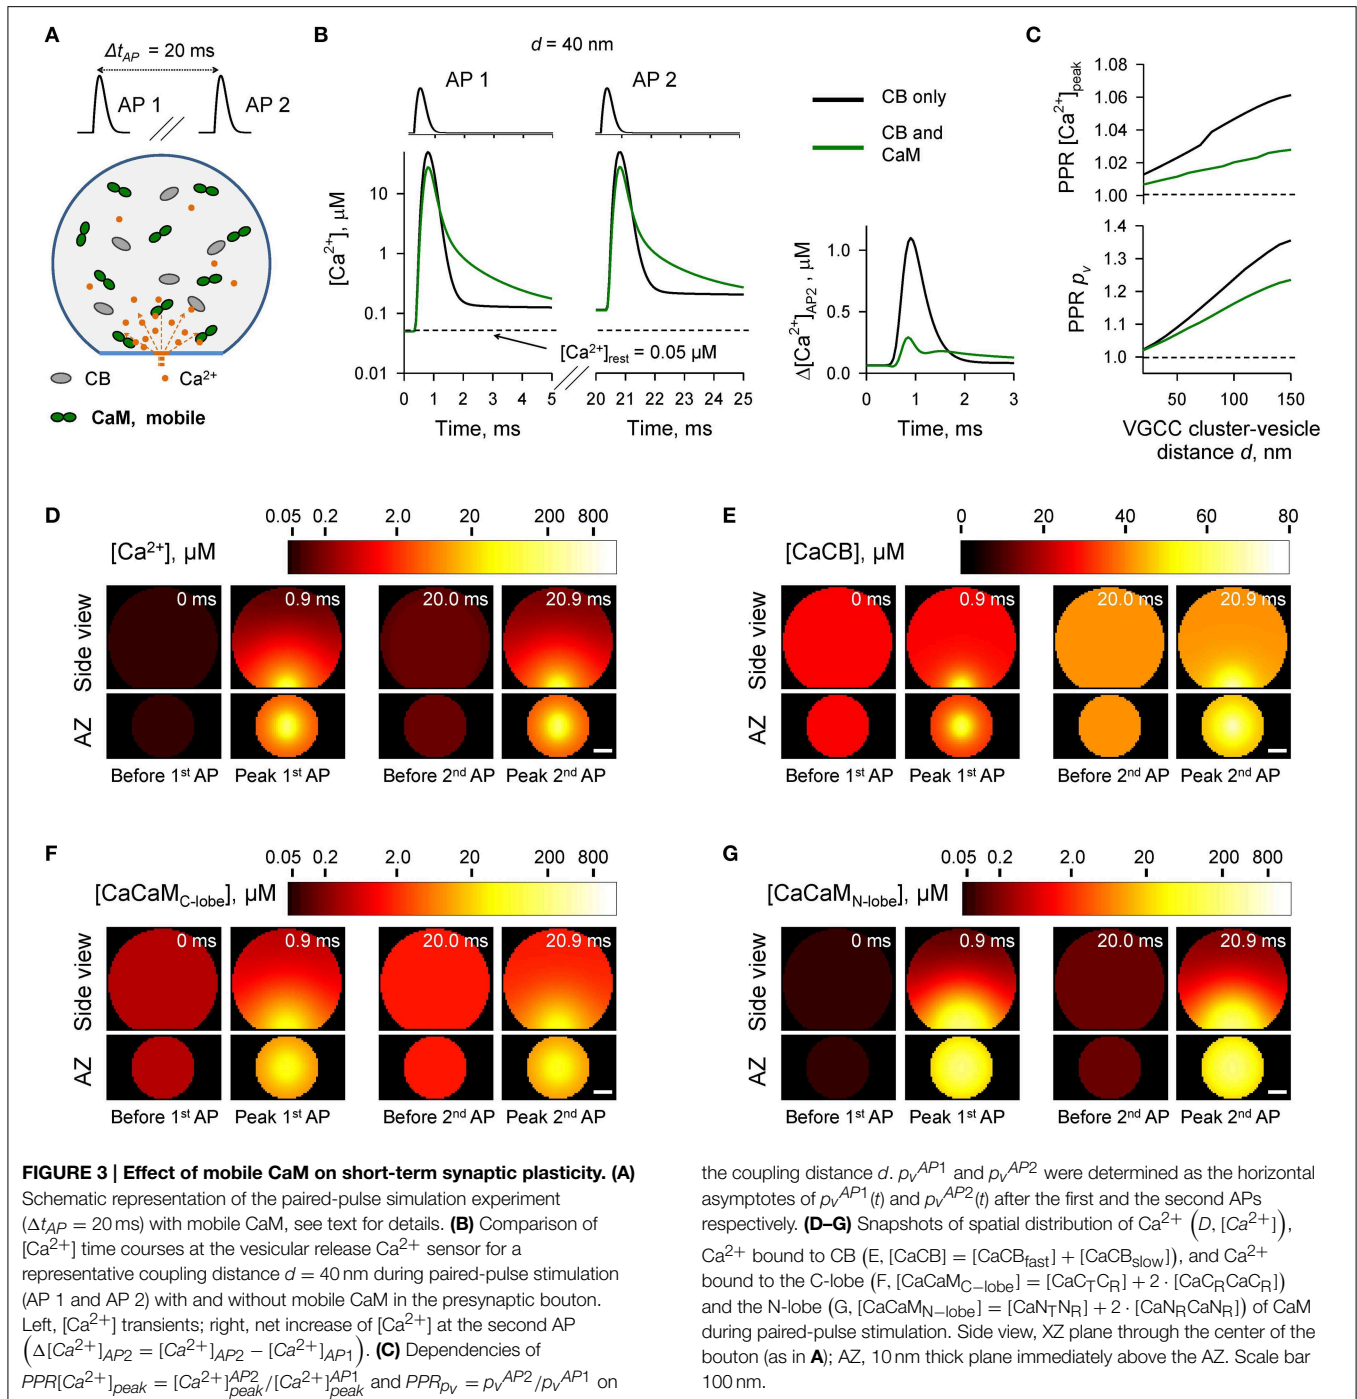

### Effect of Mobile CaM on Paired-pulse Facilitation

At certain types of central synapses CB has been shown to contribute to short-term facilitation of AP-evoked vesicular release through  $\text{Ca}^{2+}$  buffer saturation (e.g., Blatow et al., 2003; Jackson and Redman, 2003). Given the predicted dominant effect of CaM on AP-evoked release we asked how  $\text{Ca}^{2+}$  buffering by CaM affects short-term synaptic plasticity in presynaptic boutons that contain both CB and CaM. Facilitation through buffer saturation strongly depends on the mobility of the endogenous  $\text{Ca}^{2+}$  buffers (e.g., Matveev et al., 2004). CaM binds to multiple soluble and membrane-bound proteins (Xia and Storm, 2005; Villarroel et al., 2014). However, the precise distribution of presynaptic CaM molecules between the mobile and immobile

states is not known. Therefore, we explored several limiting cases with respect to the diffusional properties and spatial distribution of presynaptic CaM.

We first considered the case of mobile CaM (Figure 3, see also Figures 1, 2). We modeled  $\text{Ca}^{2+}$  dynamics and vesicular release during 50 Hz paired-pulse AP stimulation (inter-spike interval  $\Delta t_{AP} = 20$  ms) and calculated the dependencies of paired-pulse ratios (PPRs) on the coupling distance  $d$  both for peak  $[\text{Ca}^{2+}]$  ( $\text{PPR}[\text{Ca}^{2+}]_{\text{peak}} = [\text{Ca}^{2+}]_{\text{peak}}^{\text{AP2}} / [\text{Ca}^{2+}]_{\text{peak}}^{\text{AP1}}$ ) and for the vesicular release probability ( $\text{PPR}_{p_v} = p_v^{\text{AP2}} / p_v^{\text{AP1}}$ ) (Figures 3A–C). It should be noted that because we were specifically interested in the effects of CaM and CB on shaping the vesicular release, when calculating  $\text{PPR}_{p_v}$  we did not consider any changes in the number of release-ready vesicles that may occur as a result of vesicle depletion and replenishment during repetitive stimulation (Materials and Methods).

In comparison to the control simulations where only CB was present, inclusion of mobile CaM led to a noticeable decrease of both  $\text{PPR}[\text{Ca}^{2+}]_{\text{peak}}$  and  $\text{PPR}_{p_v}$  (Figure 3C). CB has a relatively high affinity to  $\text{Ca}^{2+}$  ( $K_D^{\text{eff}}_{CB} = 0.31 \mu\text{M}$ , Supplementary Figure 1) and binds  $\text{Ca}^{2+}$  ions that enter the bouton during the first AP both within the transient  $\text{Ca}^{2+}$ -nano/microdomain (local  $[\text{Ca}^{2+}]$  up to  $10\text{--}100 \mu\text{M}$  within  $20\text{--}150$  nm from the VGCC cluster) and in the rest of the bouton volume (global  $[\text{Ca}^{2+}] \sim 1.0\text{--}1.5 \mu\text{M}$ ) (Figures 3D,E). Thus, at the onset of the second AP the concentration of free CB binding sites was noticeably reduced in

comparison to the first AP (by  $\sim 10\%$ , from 163.0 to 148.5  $\mu M$ , Supplementary Figure 2). In contrast both the C- and the N-lobes of CaM have low  $Ca^{2+}$  affinities ( $K_D^{eff}{}_{C-lobe} = 2.84 \mu M$  and  $K_D^{eff}{}_{N-lobe} = 12.0 \mu M$ , Supplementary Figure 1) and bind  $Ca^{2+}$  ions mainly within the  $Ca^{2+}$ -nano/microdomain (Figures 3E,G). Therefore, because of the diffusional equilibration at the onset of the second AP over 99% of CaM  $Ca^{2+}$  binding sites at the AZ remained in the unbound state (Supplementary Figure 2). Thus,

the presence of mobile CaM, which directly competes with CB for  $Ca^{2+}$  in the AZ, occludes the short-term facilitation caused by saturation of CB.

### Effect of Immobile CaM on Paired-pulse Facilitation

In the next set of simulations (Figure 4) we considered another limiting case and assumed that all CaM molecules were immobile (e.g., bound to immobile target proteins) and were evenly

distributed throughout the bouton volume. The presence of immobile CaM still led to a reduction of paired-pulse facilitation mediated by buffer saturation, although on a smaller scale than in the case of mobile CaM (Figures 4A–C). This was due to the contribution of partial saturation of the immobile CaM C-lobe within the  $Ca^{2+}$ -nano/microdomain (Figure 4F, snapshot “Before 2<sup>nd</sup> AP”).  $Ca^{2+}$  unbinding from the fully occupied C-lobe occurs on a longer timescale ( $Ca^{2+}$  dwell time  $\sim 150$  ms,  $k_{off}^{(R),C} = 6.5 s^{-1}$ ) than the 20 ms inter-spike interval. Therefore, at a typical coupling distance  $d = 40$  nm only 80% of  $Ca^{2+}$  binding sites on the C-lobe were free at the onset of the second

AP (Supplementary Figure 3). In contrast  $Ca^{2+}$  unbinding from the N-lobe occurs on a much faster timescale ( $Ca^{2+}$  dwell time  $\sim 0.05$  ms,  $k_{off}^{(R),N} = 2.2 \times 10^4 s^{-1}$ ). Therefore, concentrations of the available N-lobe  $Ca^{2+}$  binding sites were similar at the onsets of the first and the second APs, which led to occlusion of the paired-pulse facilitation caused by saturation of CB and the C-lobe of CaM. In this set of simulations we used  $Ca^{2+}$  binding kinetics determined for free CaM (Faas et al., 2011). However, CaM  $Ca^{2+}$  binding properties are affected by binding of CaM to its target proteins. These can either increase (e.g., CaM kinase II) or decrease (e.g., neuromodulin)  $Ca^{2+}$  affinity of CaM (Gaertner

et al., 2004; Xia and Storm, 2005). Therefore, the effects of the immobile CaM on vesicular release probability  $p_v$  and short-term plasticity are expected to be also influenced by the distribution of bound CaM among different target proteins.

### The Case of Membrane-bound CaM

Many CaM binding partners are located on the presynaptic plasma membrane. In particular, neuromodulin is an abundant presynaptic protein which is found in the brain at similar levels to CaM (Alexander et al., 1988; Xia and Storm, 2005; Kumar et al., 2013). Neuromodulin is a member of the IQ motif family of CaM-binding proteins which also includes neurogranin and PEP-19 (Putkey et al., 2003; Xia and Storm, 2005). CaM binds to the IQ motif via the C-lobe at low  $[Ca^{2+}]$ , and dissociates when  $Ca^{2+}$  levels increase (Alexander et al., 1988; Xia and Storm, 2005; Kumar et al., 2013). It was proposed that at resting  $[Ca^{2+}]_{rest}$  most of presynaptic CaM is bound to the membrane anchored neuromodulin (Xia and Storm, 2005). Indeed, our model predicts that at  $[Ca^{2+}]_{rest} = 50$  nM, over 99.8% of CaM C-lobes should be in the  $Ca^{2+}$ -free apo-state which has high affinity of binding to neuromodulin.

We first considered a limiting case where all CaM molecules were irreversibly bound to neuromodulin molecules located in the bouton plasma membrane. In the VCell simulations we assumed that all CaM molecules were located within a single 10 nm layer adjacent to the plasma membrane (Figure 5). This led to  $\sim$  a ten-fold increase of  $[CaM]_{tot}$  near the plasma membrane (1023  $\mu$ M) in comparison to the case with evenly distributed CaM (100  $\mu$ M). The detailed  $Ca^{2+}$  binding kinetics to CaM associated with neuromodulin remains unknown. However, binding of CaM to the post-synaptically expressed neurogranin (which contains a similar CaM-binding IQ motif) has been shown to decrease  $Ca^{2+}$  affinity of the CaM C-lobe because of  $\sim$  a fifty-fold acceleration of  $Ca^{2+}$  dissociation rate  $k_{off}^{(R),C}$  (Gaertner et al., 2004; Hoffman et al., 2014). Therefore, in this set of simulations we also increased  $k_{off}^{(R),C}$  50-fold (from 6.5 to 325  $s^{-1}$ ).

The simulations revealed that in the case of irreversible binding of CaM to membrane associated neuromodulin, the presence of CaM still partially occludes the short-term facilitation caused by saturation of CB (Figure 5 and Supplementary Figure 4) to the degree similar to that observed in the case of evenly distributed immobile CaM (Figure 4 and Supplementary Figure 3).

### Short-term Facilitation through $Ca^{2+}$ -induced Dislocation of CaM from the Plasma Membrane

We next considered a more realistic case of dynamic  $Ca^{2+}$ -dependent interaction between CaM and neuromodulin.  $Ca^{2+}$  binding by the C-lobe of CaM reduces its affinity to neuromodulin several fold which leads to dissociation of CaM—neuromodulin complex (Alexander et al., 1988; Kumar et al., 2013; Hoffman et al., 2014). This prompts the hypothesis that  $Ca^{2+}$ -induced dislocation of CaM molecules from the membrane bound neuromodulin may decrease the  $Ca^{2+}$  buffering capacity at the AZ during repetitive AP stimulation, which, in turn,

should lead to a use-dependent increase in the vesicular release probability  $p_v$ .

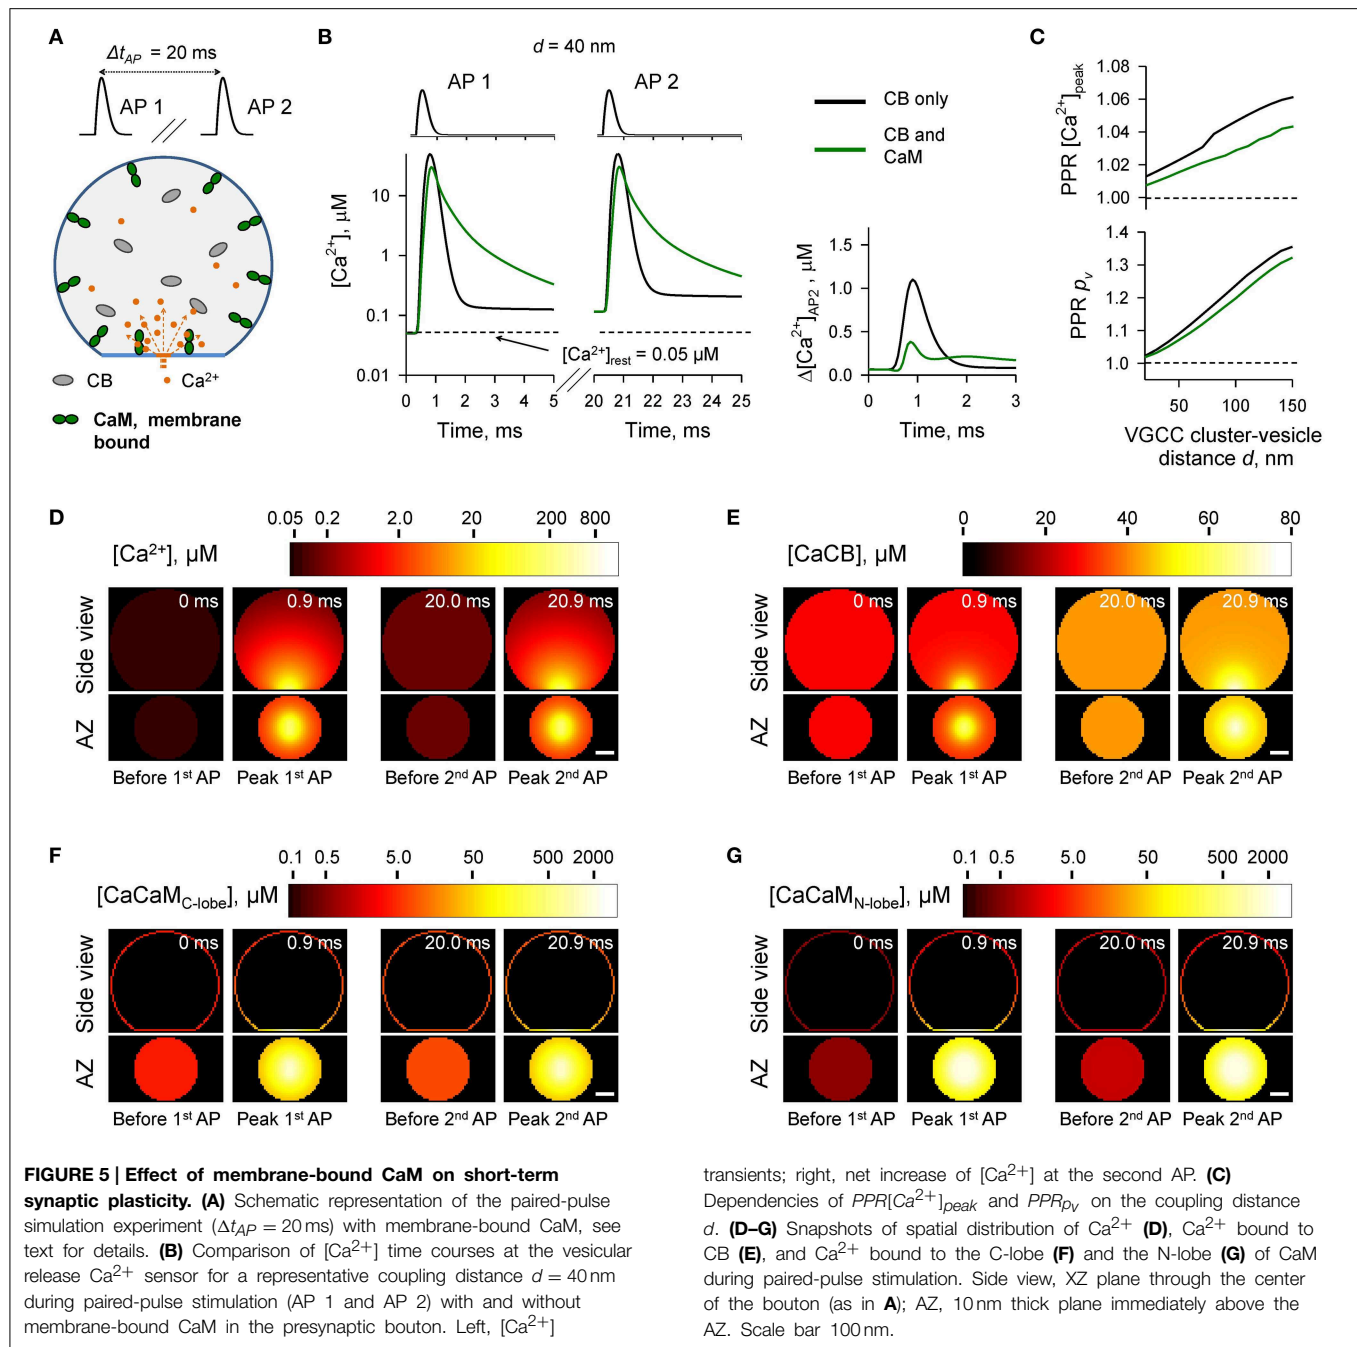

To test the feasibility of this hypothesis we modeled how  $Ca^{2+}$ -dependent dislocation of CaM molecules from the plasma membrane to the cytosol affects presynaptic  $Ca^{2+}$  dynamics and vesicular release during paired-pulse stimulation (Figure 6). As in Section The Case of Membrane-bound CaM we considered that at the beginning of each simulation ( $[Ca^{2+}]_{rest} = 50$  nM) all CaM molecules were bound to the plasma membrane via the interaction with neuromodulin. We assumed that upon binding of two  $Ca^{2+}$  ions by the C-lobe (independently of the  $Ca^{2+}$  occupancy of the N-lobe), a CaM molecule can irreversibly dissociate from the plasma membrane and freely diffuse in the cytosol (with  $D_{CaM} = 20 \mu m^2 s^{-1}$ ) (Figure 6A). The dissociation rate of the  $Ca^{2+}$  bound C-lobe from neuromodulin ( $k_{off}^{CaM}$ ) is unknown, but based on thermodynamics principles it is likely to be comparable to the effective  $Ca^{2+}$  dissociation rate. Therefore, we assumed that upon  $Ca^{2+}$  binding by the C-lobe there is a 50% chance of CaM dissociation from neuromodulin (i.e.,  $k_{off}^{CaM} = 2 \cdot k_{off}^{(R),C} = 650 s^{-1}$ ).

Simulations revealed a reduction of  $[CaM]_{tot}$  in the AZ caused by  $Ca^{2+}$  influx during the first AP (Figures 6F,G and Supplementary Figure 5). In comparison to the simulations where paired-pulse facilitation was mediated only by the buffer saturation mechanism (Figures 3–5) CaM dislocation led to a noticeably stronger increase in peak  $[Ca^{2+}]$  and  $p_v$  at the second AP (Figures 6B,C). Indeed, in the case of buffer dislocation the decrease of  $Ca^{2+}$  buffering at the second AP was not only due to saturation of the relatively slow CB and CaM C-lobe  $Ca^{2+}$  binding sites, but also due to a direct reduction in fast  $Ca^{2+}$  binding to the N-lobe of CaM, which dominates regulation of fast AP-evoked  $Ca^{2+}$ -nano/microdomain dynamics and  $p_v$  (Figure 2).

Finally we considered the effect of CaM membrane dislocation on AP-evoked release during physiological firing patterns typical for CA1 hippocampal pyramidal cells. These are characterized by short high-frequency bursts of APs that are interleaved by single APs (O'Keefe and Dostrovsky, 1971; Dobrunz and Stevens, 1999). We modeled AP-evoked presynaptic  $Ca^{2+}$  dynamics and vesicular release during a 50 Hz burst of six APs which was followed by a single AP 300 ms after the burst (Figure 7A). The results of our simulations show that cumulative dislocation of CaM from the AZ plasma membrane during the AP burst leads to a prominent and lasting longer facilitation of vesicular release, as evidently from the comparison with the control simulations where all CaM molecules were irreversibly bound to the plasma membrane (Figure 7).

## Discussion

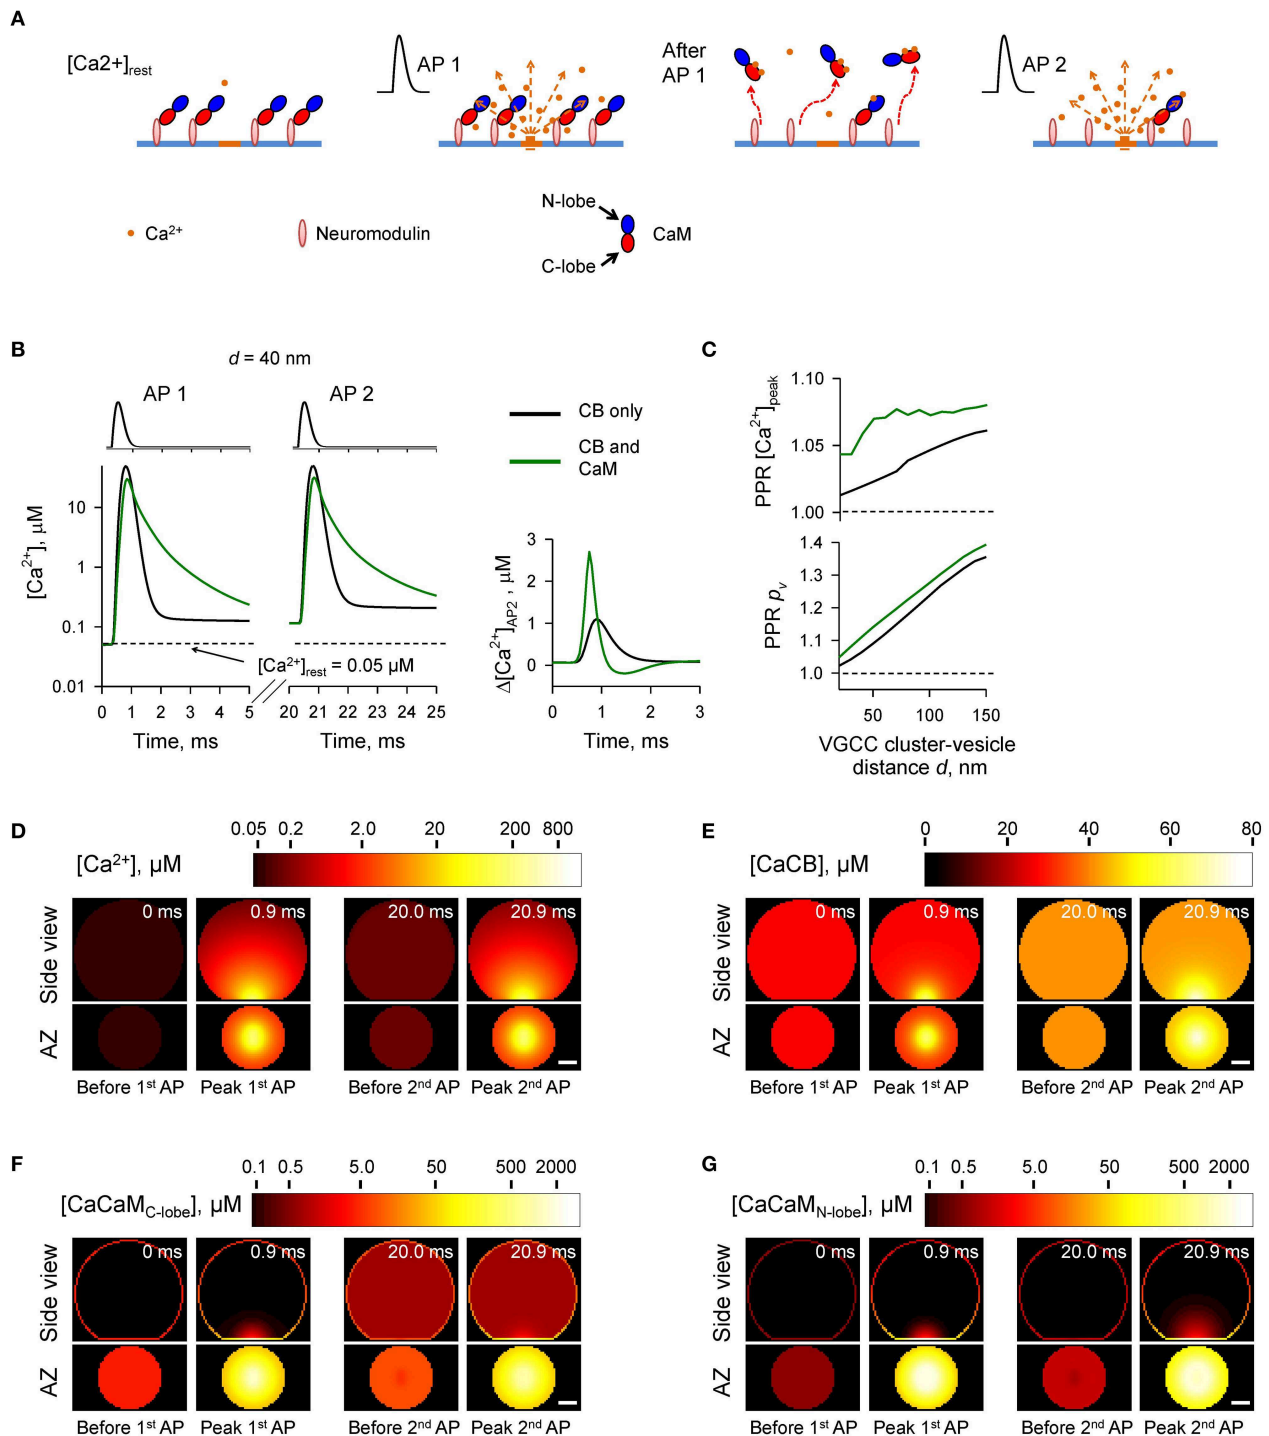

This modeling study investigates the effects of  $Ca^{2+}$  buffering by CaM on AP-evoked synaptic vesicle release and short-term synaptic plasticity. The multiple roles of CaM in modulating synaptic transmission, which it exerts via interactions with its target proteins, have been extensively characterized (Xia and Storm, 2005; Pang et al., 2010; Sun et al., 2010; Lipstein et al.,

2013; Ben-Johny and Yue, 2014). Hitherto however, the direct effects of  $Ca^{2+}$  buffering by CaM on AP-evoked presynaptic  $Ca^{2+}$  dynamics and vesicular release have not been systematically investigated.

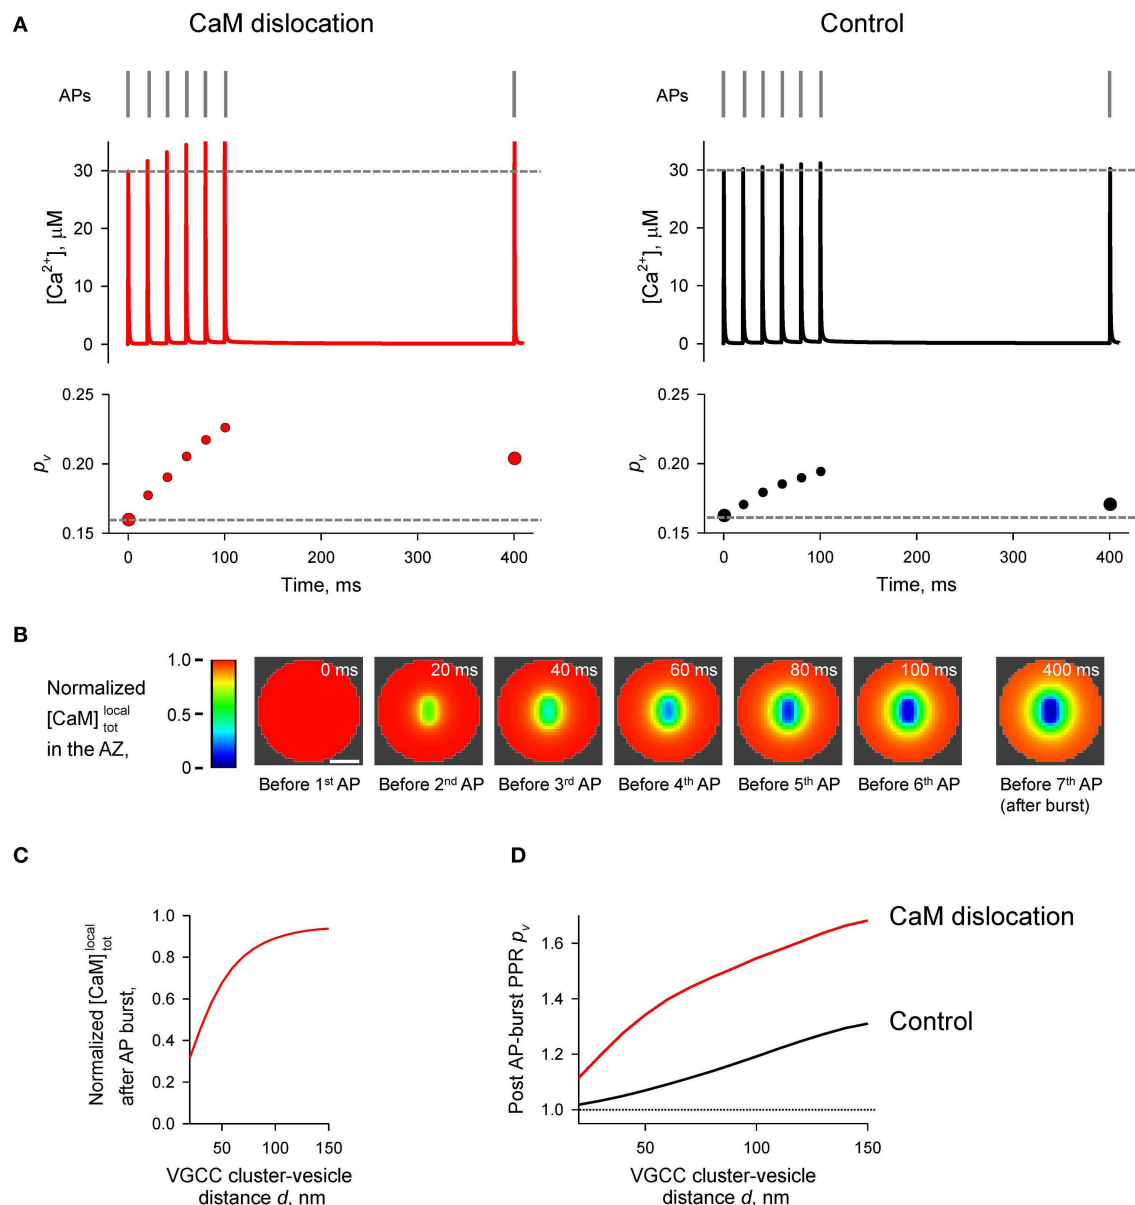

We used a realistic three-dimensional computational model of AP-evoked presynaptic  $[Ca^{2+}]$  dynamics and  $Ca^{2+}$ -triggered vesicular fusion in small excitatory synapses (Ermolyuk et al., 2013). We systematically compared the effects of physiologically relevant concentrations of CaM and CB (the two major  $Ca^{2+}$  buffers found in central excitatory synapses) on vesicular release probability and short-term synaptic plasticity. To constrain the

model parameters we used recently published detailed kinetics of  $Ca^{2+}$  binding to CaM (Faas et al., 2011), which reveal that the N-lobe of CaM binds  $Ca^{2+}$  much faster than any other characterized presynaptic  $Ca^{2+}$  buffer, whilst the CaM C-lobe binds  $Ca^{2+}$  with a rate comparable to that of CB. Consistently with this, our modeling shows that fast  $Ca^{2+}$  binding by the N-lobe of CaM plays a dominant role in shaping  $[Ca^{2+}]$  within the transient AP-evoked  $Ca^{2+}$ -nano/microdomains and as a consequence in inhibition of vesicular release probability  $p_v$ . In contrast, slower  $Ca^{2+}$  binding by the CaM C-lobe and by CB plays only a secondary role.

**FIGURE 6 |  $\text{Ca}^{2+}$ -dependent CaM dislocation from the AZ as a mechanism of short-term facilitation. (A)** Schematics depicting the model of  $\text{Ca}^{2+}$ -dependent CaM dislocation from the membrane during paired-pulse simulation experiment. We assumed that at resting  $[\text{Ca}^{2+}]_{\text{rest}}$  all CaM molecules were in the  $\text{Ca}^{2+}$ -free apo state and bound via the C-lobes to the membrane-associated neuromodulin molecules. Binding of two  $\text{Ca}^{2+}$  ions by the C-lobe during the first AP leads to its dissociation from neuromodulin and to reduction of  $\text{Ca}^{2+}$  buffering at the AZ during the second AP. **(B)** Comparison of  $[\text{Ca}^{2+}]$  time courses at the vesicular release

$\text{Ca}^{2+}$  sensor for a representative coupling distance  $d = 40 \text{ nm}$  during paired-pulse stimulation (AP 1 and AP 2) with and without CaM in the presynaptic bouton. Left,  $[\text{Ca}^{2+}]$  transients; right, net increase of  $[\text{Ca}^{2+}]$  at the second AP. **(C)** Dependencies of  $\text{PPR}[\text{Ca}^{2+}]_{\text{peak}}$  and  $\text{PPR} p_v$  on the coupling distance  $d$ . **(D–G)** Snapshots of spatial distribution of  $\text{Ca}^{2+}$  **(D)**,  $\text{Ca}^{2+}$  bound to CB **(E)**, and  $\text{Ca}^{2+}$  bound to the C-lobe **(F)** and the N-lobe **(G)** of CaM during paired-pulse stimulation. Side view, XZ plane through the center of the bouton (as in **A**); AZ, 10 nm thick plane immediately above the AZ. Scale bar 100 nm.

**FIGURE 7 | Effect of CaM dislocation on short-term facilitation during physiological patterns of AP firing. (A)** Comparison of  $Ca^{2+}$  dynamics and vesicular release probability  $p_v$  at a representative coupling distance  $d = 40$  nm for the case of  $Ca^{2+}$ -dependent CaM dislocation (left) and for the control case of irreversible membrane bound CaM (right). Top, physiological AP stimulus pattern; middle,  $[Ca^{2+}]$  time courses; bottom,  $p_v$  plots. **(B)** Snapshots of spatial distribution of normalized local total  $[CaM]_{tot}^{local}$  (which accounts for all CaM molecules in a given voxel, irrespective of their  $Ca^{2+}$

binding state) in the AZ, illustrating progressive dislocation of CaM from the AZ during the burst of APs [the same stimulation pattern as in **(A)**]. Scale bar 100 nm. **(C)** Dependency of normalized  $[CaM]_{tot}^{local}$  after the burst of APs on the coupling distance  $d$ . Normalized  $[CaM]_{tot}^{local}$  in **(B)** and **(C)** were calculated by dividing the spatially dependent  $[CaM]_{tot}^{local}$  by the initial total  $[CaM]_{tot} = 1023 \mu M$ . **(D)** Dependences of post-AP burst  $PPR_{p_v}$  on the coupling distance  $d$  calculated for the single AP at  $t = 400$  ms and for the first AP in the burst.

Our simulations also demonstrate that, depending on its mobility and location, CaM may exert opposite effects on short-term facilitation of synaptic responses. First, the fast  $Ca^{2+}$  binding/unbinding by the CaM N-lobe generally occludes paired-pulse facilitation of vesicular release caused by partial saturation of CB and the CaM C-lobe (which release  $Ca^{2+}$  on a slow time scale). Such an occlusion mechanism, and possible

differences in concentration, location and mobility of CaM may explain why  $Ca^{2+}$  saturation of CB contributes to short-term facilitation only in certain types of synapses (e.g., Blatow et al., 2003; Muller et al., 2005; Bornschein et al., 2013).

Second, we propose a novel mechanism of short-term facilitation through  $Ca^{2+}$ -induced dislocation of CaM from the plasma membrane. It is thought that at resting conditions

most of the presynaptic CaM is bound to the membrane-associated protein neuromodulin (Alexander et al., 1988; Xia and Storm, 2005). The binding occurs at low  $[Ca^{2+}]$  via interaction between the apoCaM C-lobe and the IQ-motif of neuromodulin. Upon  $Ca^{2+}$  binding by the C-lobe when  $[Ca^{2+}]$  increases this interaction becomes weaker and CaM dissociates from neuromodulin (Xia and Storm, 2005; Kumar et al., 2013). Thus, we hypothesize that transient increase of  $[Ca^{2+}]$  within  $Ca^{2+}$ -nano/microdomains may lead to a dislocation of CaM molecules from the plasma membrane at the AZ into the cytosol.

Indeed, our simulations show that even a single AP would lead to a reduction in  $[CaM]_{tot}$  in the AZ. Such a stimulation-dependent reduction of  $Ca^{2+}$  buffering capacity within the AZ results in a noticeable increase in the paired-pulse ratio when compared to the control simulation with irreversible membrane-bound CaM. The effect of  $Ca^{2+}$ -dependent CaM dislocation was even more prominent during the physiological burst-like AP firing of pyramidal cells.

When modeling the effect of  $Ca^{2+}$ -dependent CaM dislocation we assumed that the effective concentration of CaM at the membrane was  $\sim 1000 \mu M$  (to maintain the experimentally estimated  $[CaM]_{tot}$  in the entire bouton at  $100 \mu M$ ). This corresponds to  $\sim 25$  CaM molecules located at an average sized AZ with an area  $S_{AZ} = 0.04 \mu m^2$  (Schikorski and Stevens, 1997; Holderith et al., 2012). In reality it is likely that the density of CaM molecules bound at the AZ is even higher than that because at  $[Ca^{2+}]_{rest}$  apoCaM molecules are also bound to the presynaptic VGCCs via a similar IQ-motif interaction (Ben-Johny and Yue, 2014).

In this work we used a simplified model that did not take into account the mobility of VGCCs in the presynaptic membrane (Schneider et al., 2015) and also assumed irreversible dissociation of CaM from neuromodulin when both binding

sites on the CaM C-lobe were occupied by  $Ca^{2+}$  ions. Yet, the detailed kinetics of CaM and neuromodulin interaction in the presence and in the absence of  $Ca^{2+}$  remains largely unknown. Thus, further experimental and modeling work is required to obtain more realistic models of the complex kinetics of  $Ca^{2+}$ -dependent interaction of CaM with its binding partners at the AZ. Furthermore, activity-dependent phosphorylation of neuromodulin and other IQ-motif containing proteins prevents their interaction with CaM (Xia and Storm, 2005; Kumar et al., 2013). This should lead to long-lasting changes in the distribution of CaM molecules between the membrane-bound and mobile states, thus regulating  $Ca^{2+}$  buffering capacity at the AZ and  $p_v$  on a longer timescale. Our theoretical modeling study thus argues that  $Ca^{2+}$ -dependent CaM dislocation from the plasma membrane could provide a powerful mechanism for dynamic modulation of vesicular release during physiological patterns of activity, and calls for direct experimental testing of this hypothesis.
